Abstract

In this paper, we give an application of iterated pushdown automata to contour words of balls and two other domains in infinitely many tilings of the hyperbolic plane. We also give a similar application for the tiling $\{5, 3, 4\}$ of the hyperbolic $3D$ space and for the tiling $\{5, 3, 3, 4\}$ of the hyperbolic $4D$ space as well.

keywords: pushdown automata, iterated pushdown automata, tilings, hyperbolic plane, tessellations

1 Introduction

Iterated pushdown automata were introduced in [2, 9] and we refer the reader to [1] for references and for the connection of this topic with sequences of rational numbers. By their definition, iterated pushdown automata are more powerful than standard pushdown automata but they are far less powerful than Turing machines. As Turing machines can be simulated by a finite automaton with two independent stacks, iterated pushdown automata can be viewed as an intermediate device.

In this paper, we show an application of this device to the characterization of contour words of a family of bounded domains in many tilings of the hyperbolic plane. We do the same kind of application for a tiling of the hyperbolic $3D$ space and for another one in the hyperbolic $4D$ space. These two latter applications cannot be generalized to any dimension as, starting from dimension 5, there is

no tiling of the hyperbolic space which would be a tessellation generated by a regular polytope.

In section 2, we remember the definition of iterated pushdown automata with an application to the computation of the recognition of words of the form a^{f_n} , where $\{f_n\}_{n \in \mathbb{N}}$ is the Fibonacci sequence with $f_0 = f_1 = 1$. This sequence will always be denoted by $\{f_n\}_{n \in \mathbb{N}}$ in all the paper.

In section 3, we remind the reader several features and properties on tilings of the hyperbolic plane.

In section 4, we define the contour words which we are interested in and we construct iterated pushdown automata which recognize them for the case of the pentagrid and the heptagrid, *i.e.* the tilings $\{5, 4\}$ and $\{7, 3\}$ of the hyperbolic plane. We also extend these results to infinitely many tilings of the hyperbolic plane.

In section 5, we extend the result to two tilings of the 3D and 4D hyperbolic spaces.

2 Iterated pushdown automata

In this section, we fix the notations which will be used in the paper. We follow the notations of [1].

2.1 Iterated pushdown stores

This data structure is defined by induction, as follows:

$$\begin{aligned} 0\text{-pds}(\Gamma) &= \{\epsilon\} \\ k+1\text{-pds}(\Gamma) &= (\Gamma[k\text{-pds}(\Gamma)])^* \\ \text{it-psd}(\Gamma) &= \cup_k k\text{-pds}(\Gamma) \end{aligned}$$

The elements of a $k+1\text{-pds}(\Gamma)$ structure are $k\text{-pds}(\Gamma)$ structures and each element is labelled by a letter of Γ . A $k\text{-pds}(\Gamma)$ structure will often be called a k -level store, for short. When k is fixed, we speak of *outer* stores and of *inner* stores in a relative way: an i -level store is **outer** than a j -one if and only if $i < j$. In the same situation, the j -level store is **inner** than the i -one.

We define functions and operations on k -level stores, by induction on k .

From the above definition, we get that a $k+1$ -level store ω can be uniquely represented in the form:

$$\omega = A[\text{flag}].\text{rest},$$

where $A \in \Gamma$, flag is a k -level store and rest is $k+1$ -store. Moreover, if ℓ is the number of elements of rest , the number of elements of ω is $\ell+1$.

A first operation consists in defining the generalization of the standard notion of *top symbol* in an ordinary pushdown structure. This is performed by the function *topsym* defined by:

$$\begin{aligned} \text{topsym}(\epsilon) &= \epsilon \\ \text{topsym}(A[\text{flag}].\text{rest}) &= A.\text{topsym}(\text{flag}) \end{aligned}$$

It is important to remark that *topsym* is the single direct access to all inner stores of a k -level store. In other words, for any inner store, only its topmost

symbol can be accessed and when this inner store is in the top of the outest store.

Also note that the *topsym* function performs a **reading**. There are two families of **writing** operations, also concerning the elements visible from the *topmost* function only.

The first one consists of the *pop* operations defined by the following induction:

$$\begin{aligned} \text{pop}_j(\epsilon) &\text{ is undefined} \\ \text{pop}_{j+1}(A[\text{flag}].\text{rest}) &= A[\text{pop}_j(\text{flag})].\text{rest} \end{aligned}$$

The second family consists of the *push* operations defined by the following induction:

$$\begin{aligned} \text{push}_1(\gamma)(\epsilon) &= \gamma, \text{ for } \gamma \in \Gamma \\ \text{push}_j(\gamma)(\epsilon) &\text{ is undefined for } j > 1 \\ \text{push}_{j+1}(w)(A[\text{flag}].\text{rest}) &= w_1[\text{flag}]..w_k[\text{flag}].\text{rest}, \text{ where } w = w_1..w_k, \\ &\text{ with } w_i \in \Gamma \text{ for } 1 \leq i \leq k \end{aligned}$$

2.2 Iterated pushdown automata

Intuitively, the definition is very close to the traditional one of standard non-deterministic standard automata. A k -iterated pushdown automaton is defined by giving the following data:

- a finite set of states, Q ;
- an input finite alphabet Σ ;
- a store finite alphabet Γ ;
- a transition function δ from $Q \times \Sigma \cup \{\epsilon\} \times \Gamma^k$ into a finite set of instructions of the form $(q, \mathbf{op})$, where q is a state and $\mathbf{op}$ is a pop- or a push-operation as described in the previous sub-section.

We also assume that there is an initial state denoted by q_0 and that the initial state of the store is $Z[\epsilon]$, where Z is a fixed in advance symbol of Γ . Note that we allow ϵ -transition which play a key role.

A configuration is a word of the form (q, w, ω) , where q is the current state of the automaton, w is the current word and ω is the current k -level store of the automaton. A computational step of the automaton allows to go from one configuration to another by the application of one transition. In order to be applied, q state of the automaton must be that of the transition, the first letter of w must be the symbol of Σ in the transition if any, and *topsym*(ω) must be the word of Γ^k in the transition if any. A word w is accepted if and only there is a sequence of computational steps starting from $(q_0, w, Z[\epsilon])$ to a first configuration of the form (q, ϵ, ϵ) . The language recognized by a k -iterated pushdown automaton is the set of words in Σ^* which are accepted by the automaton.

As an illustrative example of the working of such an automaton, we shall take the 2-pushdown automaton given in [1], which recognizes the words of the form a^{f_n} where $\{f_n\}_{n \in \mathbb{N}}$ is the Fibonacci sequence, see the figure of automaton 1.

Now, it is not difficult to prove the following lemma:

Lemma 1 *We have the following relations, for any nonnegative k :*

$$\begin{aligned}(q_0, a^{f_k}, X_2[F^k].\omega) &\Rightarrow_{\delta}^* (q_0, \epsilon, \omega) \\ (q_0, a^{f_{k+1}}, X_1[F^k].\omega) &\Rightarrow_{\delta}^* (q_0, \epsilon, \omega)\end{aligned}$$

Proof. It is performed by induction whose basic case $k = 0$ is easy. If we start from $(q_0, a^{f_{k+1}}, X_1[F^k].\omega)$, we have the following derivation:

$$\begin{aligned}(q_0, a^{f_{k+2}}, X_1[F^{k+1}].\omega) &\vdash (q_1, a^{f_{k+2}}, X_1[F^k].\omega) \\ &\vdash (q_0, a^{f_{k+2}}, X_1[F^k].X_2[F^k].\omega) \vdash (q_0, a^{f_k}, X_2[F^k].\omega)\end{aligned}$$

by induction hypothesis as $f_{k+2} = f_{k+1} + f_k$. And, again by induction hypothesis:

$$(q_0, a^{f_k}, X_2[F^k].\omega) \vdash (q_0, \epsilon, \omega)$$

Similarly,

$$\begin{aligned}(q_0, a^{f_{k+1}}, X_2[F^{k+1}].\omega) &\vdash (q_2, a^{f_{k+1}}, X_2[F^k].\omega) \vdash (q_0, a^{f_{k+1}}, X_1[F^k].\omega) \\ &\vdash (q_0, \epsilon, \omega),\end{aligned}$$

by induction hypothesis.

Let a^m be the initial word. With the first two transitions, we guess an integer k such that $m = f_k$ if any. Then we arrive to the configuration $(q_0, a^m, Z[F^k])$. Next, we have:

$$(q_0, a^m, Z[F^k]) \vdash (q_0, a^m, X_2[F^k]).$$

And by the lemma, we proved that $(q_0, a^m, X_2[F^k]) \vdash (q_0, \epsilon, \epsilon)$ and so, the word is accepted.

We can see that if $m = f_k$ and if we guessed a wrong k , then either the word is not empty when the store vanishes, and we cannot restore it, or the word is empty as the store is not. This also shows that if $m \neq f_k$, as there is in this case a unique k such that $f_k < m < f_{k+1}$, we always have either an empty word and a non-empty store or an empty store with a nonempty word, whatever the guess. ■

three states: q_0, q_1 and q_2 ; input word in $\{a\}^*$; $\Gamma = \{Z, X_1, X_2, F\}$;
initial state: q_0 ; initial stack: $Z[\epsilon]$; transition function δ :

$$\begin{aligned}\delta(q_0, \epsilon, Z) &= \{(q_0, push_2(F)), (q_0, push_1(X_2))\} \\ \delta(q_0, \epsilon, ZF) &= \{(q_0, push_2(F)), (q_0, push_1(X_2))\} \\ \delta(q_0, \epsilon, X_1F) &= (q_1, pop_2) \\ \delta(q_0, \epsilon, X_2F) &= (q_2, pop_2) \\ \delta(q_0, a, X_1) &= (q_0, pop_1) \\ \delta(q_0, a, X_2) &= (q_0, pop_1) \\ \delta(q_1, \epsilon, X_1F) &= (q_0, push_1(X_1X_2)) \\ \delta(q_2, \epsilon, X_2F) &= (q_0, push_1(X_1)) \\ \delta(q_1, \epsilon, X_1) &= (q_0, push_1(X_1X_2)) \\ \delta(q_2, \epsilon, X_2) &= (q_0, push_1(X_1))\end{aligned}$$

3 The tilings of the hyperbolic plane

We assume that the reader is a bit familiar with hyperbolic geometry, at least with its most popular models, the Poincaré's half-plane and disc.

We remember the reader that in the hyperbolic plane, thanks to a well known theorem of Poincaré, there are infinitely many tilings which are generated by tessellation starting from a regular polygon. This means that, starting from the polygon, we recursively copy it by reflections in its sides and of the images in their sides. This family of tilings is defined by two parameters: p , the number of sides of the polygon and q , the number of polygons which can be put around a vertex without overlapping and covering any small enough neighbourhood of the vertex.

Figure 1 *Left-hand side: the pentagrid. Right-hand side: the heptagrid.*

Figure 2 *Left-hand side: the pentagrid. Right-hand side: the heptagrid. Note that in both cases, the sectors are spanned by the same tree.*

In order to represent the tilings which we shall consider and the regions whose contour word will be under study, we shall make use of the Poincaré's disc model. Our illustrations will take place in the **pentagrid** and the **heptagrid**, *i.e.* the tilings $\{5, 4\}$ and $\{7, 3\}$ respectively of the hyperbolic plane. Below, Figures 1 and 2 will illustrate these tilings.

From Figure 1, the pentagrid and the heptagrid seem rather different. However, there is a tight connection between these tilings which can be seen from Figure 2. In both pictures of the latter figure, we represent the tiling by selecting a central tile and then, by displaying as many sectors as the number of sides of the central tile. In each case, these sectors do not overlap and their union together with the central cell gives the tiling of the whole hyperbolic plane. Now, there is a deeper common point: in both cases, each sector is spanned by a tree which we call a Fibonacci tree for a reason which will soon be explained.

As proved in [3, 5], the corresponding tree can be defined as follows. We distinguish two kinds of nodes, say black nodes, labelled by B , and white nodes, labelled by W . Now, we get the sons of a node by the following rules: $B \rightarrow BW$ and $W \rightarrow BWW$, the root of the tree being a white node. It is not difficult to see that if the root is on level 0 of the tree, the number of nodes on the level k of the tree is f_{2k+1} , where $\{f_k\}_{k \in \mathbb{N}}$ is the Fibonacci sequence with $f_0 = f_1 = 1$.

Figure 3 The standard Fibonacci tree. The nodes are numbered from the root, from left to right on each level and level after level. For each node, the figure displays the representation of the number of the node with respect to the Fibonacci sequence, the representation avoiding consecutive 1's.

The Fibonacci tree has a lot of nice properties which we cannot discuss here. In particular, there is a way to locate the tiles of the pentagrid or the heptagrid very easily thanks to coordinates devised from the properties of the Fibonacci

tree, see [3, 5, 6].

4 The contour words

Now, we have the tools to define the regions from which we define contour words, and we also have the tools to define the iterated pushdown automata which recognize them.

4.1 Balls

Consider a ball B_k of radius $k+1$ in the penta- or the heptagrid. This ball is the union of the central cell and α truncated sectors, $\alpha = 5$ for the pentagrid and $\alpha = 7$ for the heptagrid, each truncated sector being spanned by a Fibonacci tree up to the level k . Accordingly, the number of tiles which are exactly at the distance $k+1$ from the central cell is $\alpha \cdot f_{2k+1}$. Denote the set of these tiles by ∂B_k .

The α sectors around the central cell can be numbered from 1 to α by fixing sector 1 once for all and by counterclockwise turning around the central cell. We call **contour word** cw_k , the word obtained by taking the labels of the tiles which are on ∂B_k , starting from the left-hand side border of sector 1 and by counter clockwise running along ∂B_k , until the tile which is on the right-hand side border of the sector α . It is easy to remark that the contour work cw_k can be written as $(sw_k)^\alpha$, where sw_k is obtained by taking the word which is on ∂B_k from the left-hand side of the sector to its right-hand side.

Figure 4 The representation of ∂B_3 . Left-hand side: the pentagrid. Right-hand side: the heptagrid. In both cases, $sw_3 = bwbwbww$.

Already by the length of the contour words, we can see that the set of all contour words is not algebraic: it is enough to apply Ogden's pumping lemma.

Now we have:

Theorem 1 *The contour words of the pentagrid and those of the heptagrid can be recognized by a 2-level pushdown automaton.*

Proof. Indeed, we can transform Automaton 1 in order to do the job. Here is the automaton:

Automaton 2 *The 2-pushdown automaton recognizing the contour word of a ball in the pentagrid or in the heptagrid.*

two states: q_0 and q_1 ; input word in $\{b, w\}^*$; $\Gamma = \{Z, B, W, F\}$;
initial state: q_0 ; initial stack: $Z[\epsilon]$; transition function δ :

$$\begin{aligned}\delta(q_0, \epsilon, Z) &= \{(q_0, push_2(F)), (q_0, push_1(W^\alpha))\} \\ \delta(q_0, \epsilon, ZF) &= \{(q_0, push_2(FF)), (q_0, push_1(W^\alpha))\} \\ \delta(q_0, \epsilon, WF) &= (q_1, pop_2) \\ \delta(q_0, \epsilon, BF) &= (q_1, pop_2) \\ \delta(q_0, b, B) &= (q_0, pop_1) \\ \delta(q_0, w, W) &= (q_0, pop_1) \\ \delta(q_1, \epsilon, WF) &= (q_0, push_1(BWW)) \\ \delta(q_1, \epsilon, BF) &= (q_0, push_1(BW)) \\ \delta(q_1, \epsilon, W) &= (q_0, push_1(BWW)) \\ \delta(q_1, \epsilon, B) &= (q_0, push_1(BW))\end{aligned}$$

Lemma 2 *We have the following relations, for any nonnegative k :*

$$\begin{aligned}(q_0, bsw_k, B[F^k].\omega) &\Rightarrow_\delta^* (q_0, \epsilon, \omega) \\ (q_0, sw_k, W[F^k].\omega) &\Rightarrow_\delta^* (q_0, \epsilon, \omega)\end{aligned}$$

where bsw_k is the word obtained on the level k of a Fibonacci tree whose root is a black node, starting from the left-hand side border to the right-hand side one.

The easy proof, strictly parallel to that of Lemma 1, is left to the reader. However, we can give an idea of the automaton which will better convince the reader.

In fact, the automaton can be seen as a device which traverse the tree in a depth first way. To this purpose, starting from the root whose height is k , the automaton puts on the outer store the nodes it takes, always going to left first. For each node, the automaton puts the labels of the sons of the node together with the height of each sons which is stored as an inner store. As the height of the sons is reduced by 1 with respect to that of the father, this obtained by a simple popping of the inner store. This explains both the construction of the automaton and its correctness.

Of course, the figure of automaton 2 provides us with two automata: one for the pentagrid and one for the heptagrid. ■

We remark from the proof that the result can be extended to any tree with a finite branching where the degree of the nodes can be defined by a fixed set of rules. A similar automaton can then be easily deduced. We refer the reader to [1] for more information on the connection between iterated pushdown automata and trees.

As proved in [7, 5], the tilings $\{p, 4\}$ and $\{p+2, 3\}$ of the hyperbolic plane are spanned by the same tree, which can be seen as a generalization of the Fibonacci tree. The tree has two kinds of nodes, again black and white, labelled by B and W respectively, as for the Fibonacci tree, and now, the rules are:

$$W \rightarrow BW^{p-3} \text{ and } B \rightarrow BW^{p-4}i. \quad (R)$$

We can define balls in the tilings $\{p, 4\}$ and $\{p+2, 3\}$ as in the case of the pentagrid or the heptagrid: it is in fact a general definition. Now, we can define also the border of a ball and the contour word which is defined as in the case of the pentagrid and of the heptagrid.

Now, considering the transitions of automaton 2, it is easy to change them in order to obtain a 2-pushdown automaton which exactly recognizes the contour words of the balls of the tilings $\{p, 4\}$ and $\{p+2, 3\}$. And so, we can state:

Theorem 2 *There is a 2-pushdown automaton which recognizes exactly the contour words of the balls of the tilings $\{p, 4\}$ and $\{p+2, 3\}$.*

4.2 Sectors

Now, we can also consider truncated sectors as a region. We can define two kinds of truncated sectors which were already studied in [5] as *quarters* and *bars* in the case of the pentagrid.

A truncated sector of the first kind, we shall say a **white k -sector**, consists of the tiles which belong to a Fibonacci tree rooted at a white tile up to the level k , this level being included. Similarly, we define a **black k -sector** using a Fibonacci tree rooted at a black node. It is plain that a white and a black k -sector can be defined indifferently in the pentagrid or in the heptagrid. Moreover, these notions can be extended to the tilings $\{p, 4\}$ and $\{p+2, 3\}$, replacing the Fibonacci tree by the tree defined by the rules (R).

The contour word of a k -sector is defined by its border, as in the case of a ball. Let W_k be a white k -sector. Then, its border, ∂W_k is defined as the set of tiles which are on the leftmost branch of the tree spanning the sector, on its rightmost branch or on the level k of the tree, see Figure 5.

Similarly, if B_k is black k -sector, its border, ∂B_k , is defined as the set of tiles which are on the leftmost branch of the tree spanning the sector, on its rightmost branch or on the level k of the tree, see Figure 6.

Now that we defined the contour words attached to ∂W_k and ∂B_k , we can prove the following result:

Theorem 3 *There is a 2-iterated pushdown automaton which recognizes the contour word of all ∂W_k 's as well as another one to recognize the contour words of all ∂B_k 's.*

Figure 5 *The representation of ∂W_3 . Left-hand side: the pentagrid. Right-hand side: the heptagrid. In both cases, the contour word is rssbwubwuwss.*

Figure 6 *The representation of ∂B_3 . Left-hand side: the pentagrid. Right-hand side: the heptagrid. In both cases, the contour word is rssbwubwuwss.*

Proof. There is no problem to recognize the leftmost branch of the tree, as it is always on the top of the store. For the rightmost branch, the idea of the proof consists in introducing new rules which will in leave on the end of the external store a witness of each node on the rightmost branch. The rules can be defined as follows:

$$\begin{aligned} W_r &\rightarrow B_b W W_b X, W_b \rightarrow B W W_b X, B_b \rightarrow B_b W, \\ W &\rightarrow B W W, B \rightarrow B W. \end{aligned}$$

Note that the second line contains the rules already used in automaton 2. The interpretation of the new rules is straightforward: W_r stands for the root, B_b for the tiles on the leftmost branch below the root, which are black nodes, W_b for the tiles on the rightmost branch below the root. Now, X is a witness left by W_b in order to remember the tile on the rightmost branch of the tree,

look at the corresponding instructions in automaton 3.

Note that automaton 3 recognizes the contour word of truncated white sectors. For truncated black sectors, it is enough to replace the rule $W_r \rightarrow B_b W W_b$ by a rule $B_r \rightarrow B_b W_r$ and to replace the transitions

$$\delta(q_0, \epsilon, Z) = \{(q_0, \text{push}_2(F)), (q_0, \text{push}_1(W_r))\},$$

$$\delta(q_0, \epsilon, ZF) = \{(q_0, \text{push}_2(FF)), (q_0, \text{push}_1(W_r))\}$$

by the transitions

$$\delta(q_0, \epsilon, Z) = \{(q_0, \text{push}_2(F)), (q_0, \text{push}_1(B_r))\},$$

$$\delta(q_0, \epsilon, ZF) = \{(q_0, \text{push}_2(FF)), (q_0, \text{push}_1(B_r))\}$$

and to change accordingly the transitions involving W_r by transitions involving B_r . The proof of the correctness of automaton 3 and the modified automaton for the truncated black sectors is straightforward and it is left to the reader.

Automaton 3 *The 2-pushdown automaton recognizing the contour word of a truncated white sector in the pentagrid or in the heptagrid.*

two states: q_0 and q_1 ; input word in $\{r, s, b, w\}^*$;

$\Gamma = \{Z, B, W, B_b, W_b, W_r, X, F\}$;

initial state: q_0 ; initial stack: $Z[\epsilon]$; transition function δ :

$$\delta(q_0, \epsilon, Z) = \{(q_0, \text{push}_2(F)), (q_0, \text{push}_1(W_r))\}$$

$$\delta(q_0, \epsilon, ZF) = \{(q_0, \text{push}_2(FF)), (q_0, \text{push}_1(W_r))\}$$

$$\delta(q_0, \epsilon, WF) = (q_1, \text{pop}_2)$$

$$\delta(q_0, \epsilon, BF) = (q_1, \text{pop}_2)$$

$$\delta(q_0, r, W_r F) = (q_1, \text{pop}_2)$$

$$\delta(q_0, r, W_r) = (q_1, \text{pop}_1)$$

$$\delta(q_0, \epsilon, W_b F) = (q_1, \text{pop}_2)$$

$$\delta(q_0, s, B_b F) = (q_1, \text{pop}_2)$$

$$\delta(q_0, b, B_b) = (q_0, \text{pop}_1)$$

$$\delta(q_0, b, B) = (q_0, \text{pop}_1)$$

$$\delta(q_0, w, W) = (q_0, \text{pop}_1)$$

$$\delta(q_0, w, W_b) = (q_0, \text{pop}_1)$$

$$\delta(q_0, s, XF) = (q_0, \text{pop}_1)$$

$$\delta(q_1, \epsilon, W_r F) = (q_0, \text{push}_1(B_b W W_r))$$

$$\delta(q_1, \epsilon, W_b F) = (q_0, \text{push}_1(B W W_r X))$$

$$\delta(q_1, \epsilon, WF) = (q_0, \text{push}_1(B W W))$$

$$\delta(q_1, \epsilon, B_b F) = (q_0, \text{push}_1(B_b W))$$

$$\delta(q_1, \epsilon, BF) = (q_0, \text{push}_1(B W))$$

■

5 Dimensions 3 and 4

We take advantage of the remark we formulated after the proof of theorem 1 in order to mention that the results of the previous section can be extended to the hyperbolic $3D$ and $4D$ spaces. As already mentioned in the introduction, there are only a few tessellations in the hyperbolic $3D$ and $4D$ spaces and, starting from dimension 5, there is no such tiling in the hyperbolic space.

We shall briefly indicate the reason why the result of theorem 1 can be extended to two tilings of the hyperbolic $3D$ and $4D$ spaces. We start with the $3D$ case first.

5.1 Dimension 3

There are four tessellations in the hyperbolic $3D$ space. We shall consider only one of them, namely the tiling $\{5, 3, 4\}$, which we shall call the **dodecagrid**, as it is built by tessellation starting from the regular dodecahedral with right angles. The numbers in the signature $\{p, q, r\}$ say that the faces have p sides, that, on a tile, q faces meet at a vertex and that any edge of a tile is shared by exactly four tiles. Such a dodecahedron is unique up to isometries of the hyperbolic $3D$ space. In [8, 5], it is proved that the dodecagrid can be split into eight sectors exactly, the eight sectors being defined by a *leading* dodecahedron. The eight leading dodecahedron share a common vertex called the **central point** and each one is in contact with exactly three of them through three of its faces. These faces of contact define three planes of the hyperbolic $3D$ space which have a common point and which are pairwise perpendicular. Now, each sector is spanned by a tree $\mathcal{T}$ whose root is associated to its leading dodecahedron.

Now, the tree $\mathcal{T}$ is a $3D$ -one which can also be represented as a planar one as its generation can be given by finitely many rules looking very much to those used in the case of the pentagrid or the heptagrid. Without entering in further details about the justification of this property, see [8, 5] for such a study, we can indicate a set of four rules which generate $\mathcal{T}$ on the basis of the labelling of each node with one of the letters O , D , C and T , the leading dodecahedron being labelled with O :

$$O \rightarrow O^5C^3T, H \rightarrow O^4C^3T, C \rightarrow O^3C^3T, T \rightarrow O^2HC^2T \quad (R_3)$$

Note that the rules can be given a matricial representation as indicated in Table 1 with self-explaining notations.

From this, using the already applied technique of the previous paragraph, it is possible to devise a 2-iterated pushdown automaton which recognize the contour words of a region whose definition is a bit changed with respect to what it was given in the previous section. Here, a ball B_k^3 of radius k is the set of tiles which are within a distance k , in tiles, from the central point. Define the border of B_k^3 , denoted by ∂B_k^3 , as the tiles which are at a distance k exactly from the central point. The contour word is defined by traversing ∂B_k^3 in the way induced by the maps defined in [8, 5]. Indeed, there is a way to injectively enumerate the tiles of the different level of $\mathcal{T}$ which allow to lift up a planar

representation of $\mathcal{T}$ as defined by the rules (R_3) up to the actual 3D-tree. This can be obtained by maps of level 1 and there is a way, described in [8, 5] to generate the map of the level k from the maps of level 1 of the different trees defined by the rules (R_3) , considering the trees rooted at each possible kind of nodes.

Table 1 *The matrix of the generating rules of dodecagrid:*

	O	H	C	T
O	5	0	3	1
H	4	0	3	1
C	3	0	3	1
T	2	1	2	1

The sectors themselves do generate a contour word. The just indicated maps can be used to identify the **sides** of the tree in the maps and the considered nodes of the tree can be given an appropriate sign. Then, the traversal defined by the extension of automaton 2 to this case will generate a contour word in which we have first the signs corresponding to the nodes which are on the sides of the sector and then the nodes which are at distance k , using the traversal defined by the maps. As we have four possible labels for the nodes, the rules (R_3) define four kinds of sectors. We shall call **k -truncated γ -sector**, with $\gamma \in \{O, H, C, T\}$, the set of tiles which belong to a tree generated by the rules (R_3) which is rooted at a tile labelled with γ .

Then we have:

Theorem 4 *There is a 2-iterated pushdown automaton which recognizes the contour words of the balls B_k in the hyperbolic 3D-space. Also, for each $\gamma \in \{O, H, C, T\}$, there is a 2-iterated pushdown automaton which recognizes the contour words of any k -truncated γ -sector.*

5.2 Dimension 4

In the hyperbolic 4D space, there are five tessellations based on a regular polytope. We shall take the one which extends the dodecagrid. From the regular dodecahedron with right angles, it is possible to construct a regular polytope called the 120-cell, whose faces are regular dodecahedra with right angles. From this regular polytope, we can generate a tiling by tessellation which we call the **120-cell grid**. The signature of this grid is $\{5, 3, 3, 4\}$ which means that four 120-cells share a common pentagon, that three dodecahedra share a common edge, and that three pentagons share a common point, five remembering that the 2-dimensional structure is a pentagon.

The common point with the dodecagrid is that the technique used for the dodecagrid also applies here. The space is the union of 16 sectors, each one having a leading 120-cell sharing a common vertex which is the central point. Each sector is spanned by a tree whose root is associated to the leading 120-cell. This tree is also generated by a finite set of rules of the same type as that of the rules (R_3). Now, this time the set of rules is much more complex as it involves 11 labels. For this reason, we shall use the matricial representation of the previous subsection with a slight modification. In Table 2, the leftmost column indicate the labels. The labels are not repeated on the first line: it is assumed that the coefficients of the matrix apply to the type of node whose label is on the row whose index is the same as the column index of the coefficient, the indices starting from 1 and the leftmost column receiving index 0. We refer the reader to [4] for the justification of these rules and for further explanations.

Table 2 *The matrix of the generating rules of the 120-cell grid:*

9	6	10	21	35	3	19	14	5	1	1	1
8	5	10	21	35	3	19	14	5	1	1	1
7	4	10	21	35	3	19	14	5	1	1	1
6a	3	11	20	35	3	19	14	5	1	1	1
6b	2	12	20	35	3	19	14	5	1	1	1
5	2	11	20	35	3	19	14	5	1	1	1
4	2	10	20	35	3	19	14	5	1	1	1
3	1	11	19	35	3	19	14	5	1	1	1
2	1	10	19	35	3	19	14	5	1	1	1
1	1	10	18	35	3	19	14	5	1	1	1
0	1	10	18	34	3	19	14	5	1	1	1

Defining the balls by the distance from a central point as in the $3D$ case, and the sectors From table 2, we can devise the instructions of a 2-iterated pushdown automaton which will recognize the contour word of a ball. We also can do the same for the k -truncated γ -sectors with $\gamma \in \{\mathbf{9,8,7,6a,6b,5,4,3,2,1,0}\}$

Acknowledgment

I wish to express special thanks to Géraud Sénizergues for drawing my attention on iterated pushdown automata and for his interest in the results of this paper.
